# Introduction I

GOAL: “To propose an algorithm to optimize the independence criterion among multivariate data using local, global, and hybrid optimizers, in conjunction with techniques involving a Lie group and its corresponding Lie algebra, for implicit imposition of the orthonormality constraint among the estimated sources”

# Introduction I

- ICA Constraint:  $WW^T = I$
- To preserve the orthogonality constraint at all time can be handled by techniques which will “lock” the weight matrix onto the constraint surface.
- The IC estimation approaches using a parameterization method such as the Lie group for implicit imposition of the orthonormality constraint, which have been reported in the literature, were designed to yield only a local optimal solution.
- Because the optimization landscape of a contrast function used for estimating the ICs of a multivariate data is nonconvex, the methods we have developed here are to look for near-global-optimum solutions.

# Contributions I

- 1 The use of global and **hybrid optimizers** in conjunction with a **Lie group**, to **maximize the independence criterion**, has never been explicitly studied before.
- 2 The issue of computational complexity is addressed, by performing the **spectral screening of the image data** prior to the IC estimation.
- 3 Recommended here is a **local optimizer**—the quasi-Newton method—employing Lie group techniques, which can yield more accurate IC estimates, compared to a conventional technique.

# Lie Group of IC Weight Matrices I

The possible IC weight matrices  $W$  belong to the set of  $n \times n$  orthogonal matrices such that  $WW^T = I$  form a **Lie group** under matrix multiplication because the following group axioms are satisfied:

- closed under matrix multiplication, associativity, identity element, and existence of an inverse;
- the group operations are differentiable;

# Lie Group of IC Weight Matrices I

- The Lie group formed by the set of  $n \times n$  orthogonal matrices with determinant  $+1$ , called the “special” orthogonal matrices  $SO(n)$ , is applied in the estimation of the ICs.
- For every  $\Theta$  lying in the space of skew-symmetric matrices  $so(n)$ , there exists a corresponding weight matrix  $W$ , which lies in the space of orthogonal matrices  $SO(n)$

$$W = \exp \Theta.$$

$$\Theta = \begin{pmatrix} 0 & a & b & c \\ -a & 0 & d & e \\ -b & -d & 0 & f \\ -c & -e & -f & 0 \end{pmatrix}$$

$$\widehat{W} = (a, b, c, d, e, f)$$

## Lie Group of IC Weight Matrices II

- The orthonormality constraint among the estimated ICs will never be violated during the course of optimization, in the proposed approach using the Lie group.

# MI as Contrast Function I

The mutual information (MI) was chosen to be the suitable contrast function, to separate the sources with mutually exclusive specific information from the multivariate data:

- The MI, expressed as the negative sum of **negentropy approximations**, is the natural measure of dependence.
- MI:

$$I(z_1, z_2, \dots, z_n) \propto - \sum_i J(z_i)$$

where  $J(z_i) \propto [E\{G(z_i)\} - E\{G(\gamma)\}]^2$  are the negentropy approximations based on the maximum-entropy principle computed for the linear combinations

$$z_i = \mathbf{w}_i^T \mathbf{x}, i = 1, 2, \dots, n$$

## MI as Contrast Function I

The nonquadratic function is selected from the following choices  $G_1$  and  $G_2$ , to compute the negentropy approximations

$$G_1(z_i) = \frac{1}{a_1} \log \cosh(a_1 z_i)$$

$$G_2(z_i) = -\frac{1}{a_2} \exp\left(-a_2 \frac{z_i^2}{2}\right)$$

The overall optimization problem is:

$$\min I(z_1, z_2, \dots, z_n) \approx -\sum_i [E\{G(z_i)\} - E\{G(\gamma)\}]^2$$

subject to the constraint  $WW^T = I$

# Local Minimization of MI with Lie Group Techniques I

MI minimization using the quasi-Newton method and the Lie group, reasons:

- 1 It uses both gradient and curvature informations about the optimization landscape during the search process,
- 2 Hessian update can be obtained using only gradient information, the computational overhead is relatively small, the method converges superlinearly, and it performs well for cases where the steepest ascent methods suffer from convergence difficulty

# Local Minimization of MI with Lie Group Techniques I

## Implementation

- The weight matrix  $\mathbf{W}_1$  corresponding to a randomly chosen representative vector  $\widehat{\mathbf{W}}_1$  of dimension  $n(n-1)/2$ ,

$$\mathbf{W}_{m+1} = \exp(-\alpha_m \Theta_{\delta_m}) \mathbf{W}_m \quad m \text{ the iteration number.}$$

- Optimum is determined by the line-search iterative technique employing the cubic/quadratic polynomial method

$$f(\mathbf{W}_{m+1}) < f(\mathbf{W}_m).$$

- The skew-symmetric matrix  $\Theta_{\delta_m}$  is constructed from the search direction  $\delta_m$

## Local Minimization of MI with Lie Group Techniques II

$$\delta_m = \mathbf{H}_m^{-1} \mathbf{g}_m.$$

- $\mathbf{H}_m$  is the Hessian update of the contrast function.  $\mathbf{g}_m$  is the representative vector of the gradient of in the Lie algebra space that is:

$$\frac{\partial I}{\partial \Theta_m} = \left( \frac{\partial I}{\partial \mathbf{W}_m} \right) \mathbf{W}_m^T - \mathbf{W}_m \left( \frac{\partial I}{\partial \mathbf{W}_m} \right)^T$$

- Hessian update:

$$\mathbf{H}_{m+1} = \mathbf{H}_m + \frac{\boldsymbol{\eta}_m \boldsymbol{\eta}_m^T}{\boldsymbol{\eta}_m^T \mathbf{s}_m} - \frac{\mathbf{g}_m \mathbf{g}_m^T}{\boldsymbol{\delta}_m^T \mathbf{g}_m}$$

$$\mathbf{s}_m = \widehat{\mathbf{W}}_{m+1} - \widehat{\mathbf{W}}_m \text{ and } \boldsymbol{\eta}_m = \mathbf{g}_{m+1} - \mathbf{g}_m$$

# Local Minimization of MI with Lie Group Techniques III

- The MI is computed as the negative sum of the negentropy approximations of the data values in each dimension.

# Outline

- 1 Introduction
- 2 Lie Group of IC Weight Matrices
- 3 MI as Contrast Function
- 4 Local Minimization of MI with Lie Group Techniques
- 5 Near-global Minimization of MI with Lie Group Techniques**
- 6 Minimization of MI using Hybrid Optimizers and Lie Group Techniques
- 7 Experimental Results and Discussion
- 8 Conclusion

# Near-global Minimization of MI with Lie Group Techniques I

- It is imperative to design the global optimizers in conjunction with the Lie group, to produce more accurate IC estimates, which are insensitive to the initial choice of the random input vectors.
  - ▶ Data processing using spectral screening
  - ▶ Simulated Annealing With Lie Group Techniques
  - ▶ Cross-Entropy Method With Lie Group Techniques

# Data processing using spectral screening I

- To make the estimation of the ICs in very large data computationally feasible with the global optimizers, instead of taking the entire set of data vectors into account, a **small subset of data vectors** can be used such that a few vectors represent each group of “similar” vectors.
- The similarity measure between the data vectors and is the **spectral angle**:

$$\alpha(\mathbf{x}, \mathbf{y}) = \cos^{-1} \left( \frac{\langle \mathbf{x}, \mathbf{y} \rangle}{\|\mathbf{x}\|_2 \|\mathbf{y}\|_2} \right).$$

- **Algorithm:**

- ▶ S: The set of all pixel vectors present in the multispectral image.
- ▶ One of the pixel vectors is placed in the subset  $S_1$ .
- ▶ Each pixel vector from is compared with all the pixel vectors already placed in  $S_1$ .

## Data processing using spectral screening II

For all  $\mathbf{x} \in S_1$ , if the similarity measure  $\alpha(\mathbf{x}, \mathbf{y})$  in (11) is greater than the angle threshold  $\beta$ , then  $\mathbf{y}$  is included in  $S_1$ ; otherwise, it is discarded. At the end of the process,  $S_1$  will contain the representative pixel vectors from  $S$  that are quite dissimilar.

# Minimization of MI using Hybrid Optimizers and Lie Group Techniques I

- There is an improvement in the quality of the solution while using the Lie group with the global optimization techniques. Problem: they are being trapped in the local minima.
- To avoid this: Hybrid optimizers.
  - ▶ PSO (global optimizer) with the quasi-Newton local optimizer during every iteration (**PSO-QN**) or at a periodic intervals (**PSO-periodic QN**).
  - ▶ FastICA (local optimizer) to minimize the MI produced by the PSO in all the iterative steps (**PSO-fastICA**) or periodically (**PSO-periodic fastICA**)

# Minimization of MI using Hybrid Optimizers and Lie Group Techniques

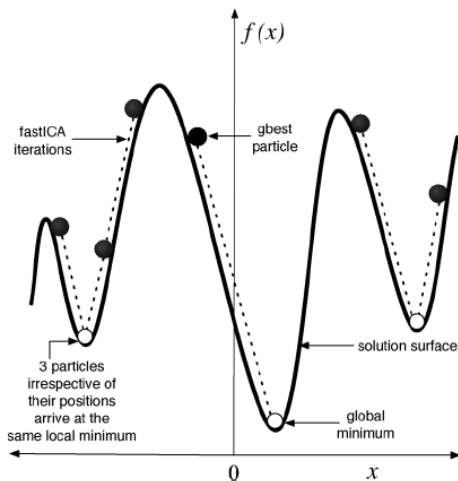

Fig. 2. Implementation of the hybrid optimizer—a combination of the PSO and fastICA.

# Minimization of MI using Hybrid Optimizers and Lie Group Techniques I

- In the PSO-QN algorithm, the quasi-Newton method minimizes the MI by treating the weight vectors ( $\widehat{W}_i(1)$ ) as the set of inputs; the resulting weight vectors related to the local minima are the updated particles' positions in the first iteration.
- In the PSO-fastICA algorithm, the weight matrices  $W_i(1)$  corresponding to  $\widehat{W}_i(1)$  serve as the inputs for the fastICA algorithm employing symmetric orthogonalization to minimize the MI.
- Instead of updating the particles' positions based on the fastICA results, the local minimum MI values are assigned to the particles' initial positions itself.
- In the periodic versions, at iteration  $k$ , the search positions  $x_i(k)$  of the particles:

# Minimization of MI using Hybrid Optimizers and Lie Group Techniques II

$$\mathbf{v}_i(k+1) = \chi [\mathbf{v}_i(k) + \varphi_1 * \mathbf{rand1}_i * (\mathbf{pbest}_i(k) - \mathbf{x}_i(k)) + \varphi_2 * \mathbf{rand2}_i * (\mathbf{gbest}(k) - \mathbf{x}_i(k))] \quad (18)$$

$$\mathbf{x}_i(k+1) = \mathbf{x}_i(k) + \mathbf{v}_i(k+1) \quad (19)$$

$$\chi = \frac{2\kappa}{|2 - \varphi - \sqrt{\varphi^2 - 4\varphi}|}$$

$$\varphi = \varphi_1 + \varphi_2, \quad \varphi > 4$$

$$\kappa \in [0, 1].$$

# Minimization of MI using Hybrid Optimizers and Lie Group Techniques

- While implementing the PSO-fastICA algorithm, the weight matrices  $W_i(k+1)$  corresponding to  $\widehat{W}_i(k+1)$  serve as the inputs for the fastICA algorithm to assign the local minimum MI values to  $x_i(k+1)$ .

# Experimental Results and Discussion

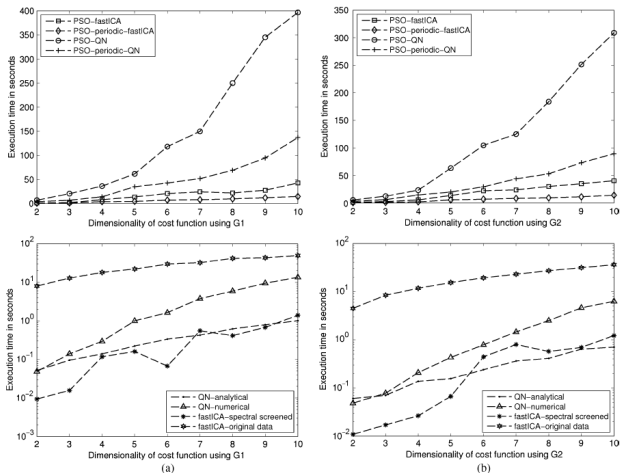

Fig. 8. Relationship between the average CPU time taken by the various algorithms, implemented with the same stopping criterion, and the data dimension: (a) using  $G_1$ ; (b) using  $G_2$ . The proposed approaches were supplied with the spectral screened input, to illustrate how the execution time of the PSO-fastICA and the PSO-periodic fastICA could be brought lower than that of the fastICA implemented with the original image input of size  $200 \times 200$ . Implementing the quasi-Newton method with the analytical gradient makes it comparable with the fastICA, and the CPU time noticeably reduces. Notice that the  $y$ -axis is logarithmic for the bottom row.

# Conclusion I

- Source separation algorithms are proposed and investigated for accurately estimating the weight matrix in the ICA model, with the help of Lie group techniques.
- We have proposed an approach to use a local optimizer, the quasi-Newton method, in conjunction with the Lie group, to impose the orthonormality constraint implicitly.
- This approach produces more accurate IC estimates in comparison with the fastICA, provided both the approaches are supplied with the same initial random input vector.
- We have attempted an approach wherein the global optimizers, the PSO, EP, SA, and CE method, are implemented with the Lie group.
- We have demonstrated how the variations of the hybrid optimizers, preserve a reasonable estimation accuracy by periodically integrating the local optimizers with the global one.
